## Abstract

At the core of fully homomorphic encryption lies a procedure to refresh the ciphertexts whose noise component has grown too big. The efficiency of the so-called *bootstrap* is of paramount importance as it is usually regarded as the main bottleneck towards a real-life deployment of fully homomorphic crypto-systems. In two of the fastest implementations so far [3, 5], the space of messages is limited to binary integers. If the message space is extended [9, 8] to the discretized torus  $\mathbb{T}_{p_i}$  or equivalently to  $\mathbb{Z}_{p_i}$  with values of  $p_i$  large as compared to the dimension of the quotient ring in which the operations are realised, the bootstrap delivers incorrect results with far too high probability. As a consequence, the use of a residue numeral system to address large integers modulo  $p = p_1 \times \dots \times p_\kappa$  would be of limited interest in practical situations [1, 2] without the following remedy : rather than increasing the polynomial degree and thus the computational cost, we introduce here a novel and simple technique (hereafter referred to as “collapsing”) which, by grouping the components of the mask, attenuates both rounding errors and computational costs, and greatly helps to sharpen the correctness of the bootstrap. We then rigorously estimate the probability of success as well as the output error and determine practical parameters to reach a given correctness threshold.

**Keywords:** homomorphic encryption, bootstrap, large integers, rounding errors, collapse, probability estimates.

## 1 Introduction

This paper is concerned with a protocol of homomorphic encryption of large integers, which combines the encoding of integers modulo

$$p = p_1 \times \dots \times p_\kappa$$

where the  $p_i$ 's are pairwise coprime, through the *Chinese Remainder Theorem* (CRT) and a FHEW-like encryption protocol [5] of a set of messages in the  $\mathbb{Z}_{p_i}$ 's. The extension – in the present context of *fully homomorphic encryption* (FHE) – of the message space from binary integers to the discretized torus with  $p_i$  messages (or equivalently  $\mathbb{Z}_{p_i}$ ) has been introduced in [9] by the authors and later on in [8] by M. Joye. However, large values of the  $p_i$ 's, which are necessary to attain 32-bits or 64-bits integers, may compromise the correctness of the bootstrapping [4, 5] operation. The main focus of this work is thus put on the analysis of

a new bootstrapping procedure, which is a modification of the FHEW/TFHE-bootstrap introduced in [4, 5], and allows for instance to handle 32-bits integers with a good level of security within the usual setting of parameters for polynomial rings of dimension  $2^{10}$  without additional computational cost.

For the sake of clarity, let us stress that nothing prevents us in principle from considering values  $p_i \geq 2$  in the usual FHEW/TFHE-bootstrap: nevertheless, the rounding process associated with the modulo switch introduces large biases that can be corrected only at the price of using ring ciphertexts with cyclotomic polynomials of large index<sup>1</sup>. This in turn renders the whole procedure computationally more costly, a particular undesirable consequence as it is already viewed as the main bottleneck of FHE. In order to allow for large values of  $p_i$  at no extra cost, we thus introduce a new technique of *collapsing*, that allows to reduce very significantly the rounding errors. Let us emphasize that, as in [7], it also allows for non-binary secret keys and that it decreases the computational cost *per se*.

We now illustrate its main idea in the TFHE setting [4]: during the first step of the bootstrapping procedure, the quantity (the so-called *phase*)

$$b - \sum_{i=1}^n s_i a_i$$

where  $(a_1, \dots, a_n) \in (\mathbb{R}/\mathbb{Z})^n$  and  $(s_1, \dots, s_n) \in \mathbb{S}^n \subset \mathbb{Z}^n$  are respectively the mask and the secret key of an incoming ciphertext  $c = (a, b)$ , should ideally be rounded to its closest value in  $\mathbb{Z}_M$ , that is to say

$$\left\lfloor M \left( b - \sum_{i=1}^n s_i a_i \right) \right\rfloor \quad (1.1)$$

where  $M$  is the index of the cyclotomic ring in which all further steps are carried. However, the components of  $s$  being secret, one has to approximate the sum (1.1) and this is usually done by substituting to (1.1) the following expression

$$\lfloor Mb \rfloor - \sum_{i=1}^n \lfloor Ms_i a_i \rfloor = \lfloor Mb \rfloor - \sum_{i=1}^n \sum_{j \in \mathbb{S}} \lfloor Mj a_i \rfloor \delta_{j, s_i} \quad (1.2)$$

(where  $\delta_{j, s_i}$  is the Kronecker symbol of  $j$  and  $s_i$ ) and resorting<sup>2</sup> to encrypted values of the  $\delta_{j, s_i}$ 's. In doing so, a large rounding bias is introduced, which can compromise the correctness of the whole bootstrapping procedure. Now, if instead of the brute-force approximation (1.1) we gather the components of the sum in (1.1) in sub-sums of  $m \geq 2$  elements<sup>3</sup>, then we obtain the more accurate approximation

$$\lfloor Mb \rfloor - \sum_{i=1}^{n/m} \sum_{j \in \mathbb{S}^m} \lfloor M(\tilde{j}_1 a_{(i-1)m+1} + \dots + \tilde{j}_m a_{im}) \rfloor \delta_{\tilde{j}, \tilde{s}_i}, \quad (1.3)$$

with  $\tilde{s}_i = (s_{(i-1)m+1}, \dots, s_{im})$  for  $i = 1, \dots, n/m$ , where we used the generalized Kronecker symbol

$$\delta_{\tilde{j}, \tilde{s}} = 1 \text{ iff } \tilde{j} = \tilde{s} \in \mathbb{S}^m$$

<sup>1</sup>We shall consider here polynomial rings of the form  $\mathbb{Q}[X]/\Phi_M(X)$  for values of  $M$  which are powers of two. Other choices are possible without fundamentally affecting the technique described here.

<sup>2</sup>Note that whenever  $\mathbb{S} = \{0, 1\}$ , then the sum takes the more common form  $\lfloor Mb \rfloor - \sum_{i=1}^n \lfloor Ma_i \rfloor \delta_{1, s_i}$ .

<sup>3</sup>For the sake of convenience, we assume here that  $m$  divides  $n$ .

and where now encrypted values of the  $\delta_{j,\tilde{s}_i}$ 's are required. It is clear that the larger  $m$  is, the more accurate (1.3) becomes and the more computationally costly the internal sum grows. Note that for  $m = 1$ , the two sums (1.2) and (1.3) coincide while for  $m = n$ , the two sums (1.1) and (1.2) coincide, i.e. the approximation (1.3) becomes exact... and computationally intractable. Besides computational aspects, it is worth emphasizing that the number of  $\delta_{j,\tilde{s}_i}$ 's that need to be encrypted and publicly released, increases exponentially fast with  $m$  (more precisely like  $n/m \cdot |\mathbb{S}|^m$ ) : alongside the computational cost of the inner loops of (1.3), this factor plays an important role to determine  $m$ . However, we will see that for moderate values of  $m$  (say from 2 to 5) an efficient trade-off can be obtained. To this aim, we will analyse rigorously the probability of correctness of the new complete bootstrapping procedure and show that it is possible to ensure that incorrect bootstrap remain extremely rare for realistic parameters. Our new *collapsing technique* appears to be necessary in this context to attain large values of  $p_i$  and thus the homomorphic treatment of large integers.

In Section 2, we define the encoding protocol for large numbers as well as the TFHE-encryption and introduce some standard definitions for the homomorphic operations that are required here. In Section 3, we give a brief description of the bootstrapping, first for cleartexts, and then for ciphertexts where the modifications that we propose come into play. In Section 4, we estimate the variance of the error of the bootstrap output. Eventually, Section 5 is devoted to the statement of Proposition 5.2 which gives accurate estimates of the probability of correctness of the new bootstrap. The comparative advantage of this new estimate is illustrated by means of several numerical experiments. As an example of application of our results, the size of the standard deviation  $\sigma$  used for encryption is assessed for different values of the ring-dimension of the security parameter with aid of the *lattice estimator*<sup>4</sup>. The corresponding correctness probabilities may be then read from the figures given here and the parameters calibrated accordingly.

## 2 The chinese remainder theorem and the encryption scheme

Our homomorphic scheme is based on homomorphic multi-modular arithmetic, where large integers are described by a Residue Number System (RNS), owing to the Chinese Remainder Theorem (CRT). For modular operations such as addition, subtraction and multiplication, the computations with residues are independent with each other, which provides parallel, carry-free homomorphic arithmetic. However, non-modular operations that require the determination of magnitudes (e.g., number comparison, overflow detection, and general division) do not have a parallel form in RNS and need specific adaptations in order to get homomorphic counterparts [1, 2].

### 2.1 Notations

In this subsection, we introduce a series of useful notations and the parameters of our cryptographic system. The scalar product of two vectors  $a$  and  $b$  is denoted by  $a \cdot b$ . The space for secret keys will be denoted by  $\mathbb{S} \subset \mathbb{Z}$  (for instance  $\mathbb{S} = \{0, 1\}$  for binary keys or  $\mathbb{S} = \{-1, 0, 1\}$  for ternary keys), its cardinal being  $|\mathbb{S}|$ .

<sup>4</sup><https://github.com/malb/lattice-estimator>

For all  $m \in \mathbb{N}^*$ , the  $m$ -rounding (half up) of a real number  $x \in \mathbb{R}$  is defined by

$$\lfloor x \rfloor_m = \left\lfloor \frac{x}{m} \right\rfloor m = \left\lfloor \frac{x}{m} + \frac{1}{2} \right\rfloor m,$$

which ensures that the associated residue  $x \bmod m := x - \lfloor x \rfloor_m$  belongs to the interval

$$I_m = [-\lfloor m/2 \rfloor, \lfloor (m-1)/2 \rfloor].$$

### Algebraic structures

Denoting  $\mathbb{Z}_m = \mathbb{Z}/m\mathbb{Z}$ , we shall consider the ring  $(\mathbb{Z}_m, +, \times)$ . For all  $x \in \mathbb{Z}_m$ , its privileged representative will be  $x \bmod m \in \mathbb{I}_m = I_m \cap \mathbb{Z}$  (throughout this paper, when no confusion is possible, we will identify a class of  $\mathbb{Z}_m$  and its representative). When  $m_i$  is a divisor of  $m$ , one can also define  $x \bmod m_i \in \mathbb{I}_{m_i}$  (which is independent of the chosen representative of the class  $x$ ). We will also consider the torus  $\mathbb{T} = \mathbb{R}/\mathbb{Z}$ , which is not a ring but is endowed with a  $\mathbb{Z}$ -module structure, equipped with the addition  $+$  and the external product  $\cdot$  with integers. The discrete torus  $\mathbb{T}_m$  is defined by  $\mathbb{T}_m = \frac{1}{m}\mathbb{Z}_m$  and will be considered as a subset of  $\mathbb{T}$ .

For all  $x \in \mathbb{R}$ , we denote by  $\pi_m(x)$  its projection on  $\mathbb{T}_m$ , which is the element of  $\mathbb{T}$  whose representative is  $\lfloor mx \rfloor / m \bmod 1$ . Noticing that the result does not depend on the choice of the representative, this definition naturally extends to  $x \in \mathbb{T}$ . Moreover, this projector will also be applied to polynomials, coefficient by coefficient. Considering now two integers  $q > p \geq 2$ , we assume, in order to ease the presentation, that  $p$  divides  $q$ , so that

$$\mathbb{T}_p = \{i/p, \quad 0 \leq i \leq p-1\} \subset \mathbb{T}_q$$

is composed of exactly  $p$  elements. Nevertheless, our discussion and results can be easily adapted to the general situation where  $p \nmid q$ .

For  $N \in \mathbb{N}^*$  a power of 2 and  $m \in \mathbb{N}^*$ , we consider the  $2N$ -th cyclotomic polynomial  $X^N + 1$  and the polynomial rings

$$\mathbb{T}_N[X] = \mathbb{T}[X]/(X^N + 1), \quad \mathbb{T}_{N,m}[X] = \mathbb{T}_m[X]/(X^N + 1).$$

The set of polynomials of  $\mathbb{Z}_N[X] := \mathbb{Z}[X]/(X^N + 1)$  with coefficients in  $\mathbb{S}$  will be denoted by  $\mathbb{S}_N[X]$ . For all  $P = \sum_{i=0}^{N-1} P_i X^i \in \mathbb{Z}_N[X]$ , we shall denote  $\|P\|_2^2 = \sum_{i=0}^{N-1} P_i^2$ .

### Probability distributions

Our cryptographic system will rely on random distributions. If  $B$  is a finite set,  $a \stackrel{\mathbb{S}}{\leftarrow} B$  indicates that  $a$  is sampled uniformly in  $B$ . For  $\sigma \in \mathbb{R}_+^*$  and  $x \in \mathbb{R}$ , we denote by  $\rho_\sigma(x) = \exp(-x^2/2\sigma^2)$  the centered Gaussian with standard deviation  $\sigma$ . If  $S$  is a subset of  $\mathbb{R}$ , then  $\rho_\sigma(S)$  denotes  $\sum_{x \in S} \rho_\sigma(x)$  if  $S$  is discrete, or  $\int_S \rho_\sigma(x) dx$ , if  $S$  is Lebesgue measurable.

Let  $M$  a (continuous or discrete) closed additive subgroup of  $\mathbb{R}$ . We define on  $M$  a restricted centered Gaussian distribution  $\mathcal{D}_{M,\sigma}$  of standard deviation  $\sigma$  over  $M$  with the density function  $\mathcal{D}_{M,\sigma}(x) = \rho_\sigma(x)/\rho_\sigma(M)$ . If  $L$  is a discrete subgroup of  $M$ , then the modular Gaussian distribution  $\mathcal{D}_{M/L,\sigma}$  over  $M/L$  exists and is defined by the density  $\mathcal{D}_{M/L,\sigma}(x) = \mathcal{D}_{M,\sigma}(x)(x+L)$ .

In particular, this defines the modular Gaussian distribution  $\mathcal{D}_{\mathbb{T}_q, \sigma}$  over  $\mathbb{T}_q$ . Sampling polynomials according to the corresponding distribution  $\mathcal{D}_{\mathbb{T}_{N,q}, \sigma}$  will be done coefficient by coefficient.

### The RNS representation

Consider a set of  $\kappa$  pairwise relatively prime integers  $p_1, p_2, \dots, p_\kappa$ , also referred to as the moduli, and denote their product by  $p$ . In the corresponding RNS, a modulo  $p$  integer  $x \in \mathbb{Z}_p$  is represented unambiguously by the set of residues  $x_i = x \bmod p_i \in \mathbb{I}_{p_i}$ . The  $\kappa$ -tuple

$$(x_1, x_2, \dots, x_\kappa) \in \mathbb{Z}_{p_1} \times \mathbb{Z}_{p_2} \times \dots \times \mathbb{Z}_{p_\kappa}$$

will be called the RNS representation of  $x$ . Note that, by virtue of the CRT, conversion from residues  $(x_1, x_2, \dots, x_\kappa)$  back to the modulo  $p$  of the integer  $x$  can be done as follows:

$$x = \sum_{i=1}^{\kappa} v_i \widehat{p}_i x_i \bmod p,$$

where  $v_i$  is the inverse of  $\widehat{p}_i = p/p_i$  in  $\mathbb{Z}_{p_i}$  thanks to the Bezout relation

$$(u_i p_i + v_i \widehat{p}_i) \bmod p = 1.$$

Since addition, subtraction and multiplication are modular operations, we have, for all  $(x, y) \in \mathbb{Z}_p^2$ , for  $\circ \in \{+, -, \times\}$  and for  $i \in \{1, \dots, \kappa\}$ ,

$$(x \circ y) \bmod p_i = (x \bmod p_i) \circ (y \bmod p_i) \bmod p_i.$$

## 2.2 Encryption schemes in the torus

In this section, we recall several basic schemes of TFHE [3, 4] that will be used in our construction. We first define  $(q, n, \sigma, \mathbb{S})$  such that the LWE problem on  $\mathbb{Z}_q$ , of size  $n$ , with keys uniformly sampled in  $\mathbb{S}$  and with normal error distribution  $\mathcal{N}(0, (\sigma q)^2)$  has a security parameter  $\lambda$ .

### EncryptLWE $_s(\mu)$

The TLWE encryption of  $\mu \in \mathbb{T}_q$  with the key  $s \in \mathbb{S}^n$  is defined as

$$c \leftarrow \text{TLWE}_s(\mu) = (a_1, \dots, a_n, b) \in \mathbb{T}_q^{n+1}$$

where

$$\begin{cases} a = (a_1, \dots, a_n) \xleftarrow{\$} \mathbb{T}_q^n \\ e \leftarrow \mathcal{D}_{\mathbb{T}_q, \sigma} \\ b = a \cdot s + \mu + e. \end{cases}$$

We shall use the notation  $\text{Err}(c) := e$ .

**DecryptLWE<sub>s</sub>(c, p<sub>i</sub>)**

To decrypt  $c = (a_1, \dots, a_n, b) \in \mathbb{T}_q^{n+1}$  in the plaintext space  $\mathbb{T}_{p_i}$  with the key  $s \in \mathbb{S}^n$ , return

$$\pi_{p_i}(b - a \cdot s) \in \mathbb{T}_{p_i}.$$

Similarly, let us introduce the RLWE encryption. We define  $(q, N, \sigma, \mathbb{S}_N[X])$  such that the RLWE problem on  $\mathbb{Z}_{N,q}(X)$ , with keys uniformly sampled in  $\mathbb{S}_N(X)$  and with normal error distribution  $\mathcal{N}(0, (\sigma q)^2)$  has a security parameter  $\lambda$ .

**EncryptRLWE<sub>s</sub>(μ)**

The TRLWE encryption of  $\mu \in \mathbb{T}_{N,q}[X]$  with the key  $s \in (\mathbb{S}_N[X])^{\mathbf{k}}$  is defined as

$$c \leftarrow \text{TRLWE}_s(\mu) = (a_1(X), \dots, a_{\mathbf{k}}(X), b(X)) \in \mathbb{T}_{N,q}[X]^{\mathbf{k}+1}$$

where

$$\begin{cases} a_j(X) \xleftarrow{\$} \mathbb{T}_{N,q}[X], & j = 1, \dots, \mathbf{k} \\ e(X) \leftarrow \mathcal{D}_{\mathbb{T}_{N,q}, \sigma} \\ b(X) = \sum_{j=1}^{\mathbf{k}} a_j(X) s_j(X) + \mu(X) + e(X). \end{cases}$$

We shall also use the notation  $\text{Err}(c) := e$  in this context of polynomial ciphertexts.

**DecryptRLWE<sub>s</sub>(c, p<sub>i</sub>)**

To decrypt  $c = (a_1(X), \dots, a_{\mathbf{k}}(X), b(X)) \in \mathbb{T}_{N,q}[X]^{\mathbf{k}+1}$  in the plaintext space  $\mathbb{T}_{N,p_i}[x]$  with the key  $s \in (\mathbb{S}_N[X])^{\mathbf{k}}$ , return

$$\pi_{p_i} \left( b(X) - \sum_{j=1}^{\mathbf{k}} a_j(X) s_j(X) \right) \in \mathbb{T}_{N,p_i}[x].$$

**EncryptRGSW<sub>s</sub>(m)**

Given positive integers  $B, \ell$ , the TRGSW encryption of  $m \in \mathbb{Z}_{N,q}[X]$  with the key  $s \in (\mathbb{S}_N[X])^{\mathbf{k}}$  is defined as

$$C \leftarrow \text{TRGSW}_s(m) = Z + mH_{B,\ell} \in \mathcal{M}_{(\mathbf{k}+1)\ell, \mathbf{k}+1}(\mathbb{T}_{N,q}[X])$$

where the  $(\mathbf{k}+1)\ell$  rows of  $Z$  are occurrences of  $\text{TRLWE}_s(0)$  and  $H_{B,\ell}$  is the gadget matrix

$$H_{B,\ell} = I_{\mathbf{k}+1} \otimes g \quad \text{with} \quad g = (B^{-1}, \dots, B^{-\ell})^T.$$

**2.3 Encoding and encrypting integers**

The core of our encryption is the following private-key LWE encryption/decryption scheme, with the bit-precision  $q$ .

**Encode( $m$ )**

The encoding of a message  $m \in \mathcal{M}$  is

$$\boldsymbol{\mu} = (m_1/p_1, \dots, m_\kappa/p_\kappa) \in \mathbb{T}_{p_1} \times \dots \times \mathbb{T}_{p_\kappa},$$

with  $m_i = m \bmod p_i$  for  $i = 1, \dots, \kappa$ .

**Encrypt<sub>s</sub>( $\mu$ )**

The encryption of  $\boldsymbol{\mu} \in \mathbb{T}_{p_1} \times \dots \times \mathbb{T}_{p_\kappa}$  is the vector  $\mathbf{c} = (c_1, \dots, c_\kappa) \in (\mathbb{T}_q^{n+1})^\kappa$ , where  $c_i = \text{EncryptTLWE}_s(\pi_q(\mu_i))$  for  $i = 1, \dots, \kappa$ .

**Decrypt<sub>s</sub>( $c$ )**

The decryption of  $\mathbf{c} = (c_1, \dots, c_\kappa) \in (\mathbb{T}_q^{n+1})^\kappa$  is the vector  $\boldsymbol{\mu} = (\mu_1, \dots, \mu_\kappa) \in \mathbb{T}_{p_1} \times \dots \times \mathbb{T}_{p_\kappa}$ , where  $\mu_i = \text{DecryptTLWE}_s(c_i, p_i)$  for  $i = 1, \dots, \kappa$ .

**Decode( $\mu$ )**

The vector  $\boldsymbol{\mu} = (\mu_1, \dots, \mu_\kappa) \in \mathbb{T}_{p_1} \times \dots \times \mathbb{T}_{p_\kappa}$  is decoded into

$$m = \left( p \sum_{i=1}^{\kappa} v_i \cdot \mu_i \right) \bmod p.$$

**2.4 Homomorphic operations on ciphertexts****2.4.1 Homomorphic addition**

We denote unambiguously by  $\oplus$  the addition of both T(R)LWE-ciphertexts and TRGSW-ciphertexts. We recall that, if  $c_1$  and  $c_2$  are two T(R)LWE-ciphertexts, i.e.

$$c_1 = \text{T(R)LWE}_s(\mu_1) \text{ and } c_2 = \text{T(R)LWE}_s(\mu_2),$$

then

$$c_1 \oplus c_2 = \text{T(R)LWE}_s(\mu_1 + \mu_2)$$

where the equality means that

$$\text{Decrypt(R)LWE}_s(c_1 \oplus c_2, p_i) = \mu_1 + \mu_2.$$

Similarly, if  $C_1$  and  $C_2$  are two TRGSW-ciphertexts, i.e.

$$C_1 = \text{TRGSW}_s(m_1) \text{ and } C_2 = \text{TRGSW}_s(m_2)$$

then

$$C_1 \oplus C_2 = \text{TRGSW}_s(m_1 + m_2)$$

where the equality means that both sides are (possibly different) encryptions of  $m_1 + m_2$ .

### 2.4.2 Homomorphic modular product

We recall that the  $\mathbb{Z}_{N,q}[X]$ -module  $\mathbb{T}_{N,q}[X]$  is by definition endowed with a *modular* product  $\cdot$  whose counterpart on TRGSW-ciphertexts is the co-called *external* product  $\boxtimes$ . Besides, if

$$C = \text{TRGSW}_s(m) \text{ and } c = \text{TRLWE}_s(\mu),$$

then

$$C \boxtimes c = \text{TRLWE}_s(m \cdot \mu)$$

in the sense that

$$\text{DecryptRLWE}_s(C \boxtimes c) = m \cdot \mu.$$

The effective external product of  $C$  and  $c$  is obtained through the vector-matrix multiplication

$$C \boxtimes c = \text{dec}_{B,\ell}(c) C$$

where  $\text{dec}_{B,\ell}(c) = (\text{dec}_{B,\ell}(a_1(X)), \dots, \text{dec}_{B,\ell}(a_{\mathbf{k}}(X)), \text{dec}_{B,\ell}(b(X)))$

$$\text{dec}_{B,\ell}(a_j(X)) = \left( \sum_{r=0}^{N-1} \text{dec}_{B,\ell}(a_{j,r})_1 X^r, \dots, \sum_{r=0}^{N-1} \text{dec}_{B,\ell}(a_{j,r})_\ell X^r \right)$$

with for all  $x \in \mathbb{T} \equiv [-\frac{1}{2}, \frac{1}{2}[$

$$x = \sum_{t=1}^{\ell} \text{dec}_{B,\ell}(x)_t B^{-t} - \delta(x), \quad \text{dec}_{B,\ell}(x)_t \in \{-B/2, \dots, B/2\}, \quad |\delta(x)| \leq \frac{B^{-\ell}}{2}.$$

## 3 Bootstrapping in $\mathbb{T}_{p_i}$

In the same line as most FHE libraries, RHE protocol relies on hard lattice problems: in order to ensure the security of encryption, a noise is added in the ciphertext. During the course of arithmetic operations, this noise accumulates up to a level where it overwhelms the message itself and prevents a correct decryption. In order to avoid this deadlock, an *ad-hoc* procedure, introduced in 2009 by Gentry [6] and named *bootstrapping*, has been specially designed to reduce the noise to an acceptable level, thus permitting further computations. Generally speaking, Gentry's concept consists in a sequence of homomorphic operations that emulate the decryption procedure. However, in our context the rounding operation inherent to the decryption formula

$$\mu' = \frac{\lfloor p_i(b - a \cdot s) \rfloor}{p_i} \bmod 1, \tag{3.1}$$

(which coincides with  $\mu \in \mathbb{T}_{p_i}$  as long as  $|e| < \frac{1}{2p_i}$ ) prevents a direct implementation of the Gentry's strategy starting from this formula.

In order to remedy this problem, Ducas and Micciancio [5], and later on in a faster version, Chillotti et al. [3, 4], have introduced a very efficient bootstrapping based on the use of polynomials. In the rest of this section, we present the extension of this procedure to the case of messages in the discrete torus  $\mathbb{T}_{p_i}$ . In order to keep the rounding errors as small as possible, we resort to a simple technique (referred to as *collapsing*) which we incorporate into the original procedure of [3].

### 3.1 The construction for cleartexts

Consider, for any  $v(X) = \sum_{j=0}^{N-1} v_j X^j$  in the  $\mathbb{Z}_{N,q}[X]$ -modulus  $\mathbb{T}_{N,q}[X]$ , the function

$$\begin{aligned} f_v : \mathbb{Z} &\rightarrow \mathbb{T}_q \\ j &\mapsto f_v(j) = (-1)^{\lfloor \frac{j}{N} \rfloor} v_{N \lfloor \frac{j}{N} \rfloor - j} \end{aligned}$$

It can be easily checked that  $f_v(-j) = v_j$  and that  $f_v(j)$  is simply the constant coefficient of the modular product  $X^j \cdot v(X)$  for  $0 \leq j \leq N - 1$ . Now, the underlying idea of the bootstrapping procedure of [5, 3] consists in the homomorphic implementation of the function

$$\mu \in \mathbb{T}_q \mapsto f_v(\lfloor 2N\mu \rfloor) = \text{coeff}_0 \left( X^{\lfloor 2N\mu \rfloor} \cdot v(X) \right)$$

where  $\text{coeff}_0$  selects the constant term of a polynomial and where the so-called *test-polynomial*  $v$  is chosen so as to ensure that  $\mu \mapsto f_v(\lfloor 2N\mu \rfloor)$  is almost the identity function on  $\mathbb{T}_{p_i}$  in the sense that

$$\forall \mu \in \mathbb{T}_{p_i}, \quad f_v(\lfloor 2N(\mu + e) \rfloor) = \mu \quad (3.2)$$

for small enough  $e$ .

**Remark 3.1** *One could replace the right-hand side of (3.2) by  $g(\mu)$  for any function  $g$  from  $\mathbb{T}_{p_i}$  to itself, provided*

$$\forall (\mu, \nu) \in \mathbb{T}_{p_i}^2, \quad \min_{k \in \mathbb{Z}} \left| \mu - \nu + \frac{k}{2} \right| > 0,$$

*a condition satisfied e.g. for odd  $p_i$ 's.*

Formula (3.2) for  $e = 0$  is generally not enough *per se* to define the coefficients of  $v$ . In order to increase the tolerance with respect to errors (i.e. to enforce (3.2) for values of  $e$  as large as possible), we choose to define the  $v_j$ 's as follows

$$\forall j = 0, \dots, N - 1, \quad v_j = (-1)^{\lfloor \frac{j}{N} \rfloor} \frac{\lfloor \frac{j}{N} \rfloor}{2p} - \frac{1}{2} \left( 1 - (-1)^{\lfloor \frac{j}{N} \rfloor} \right). \quad (3.3)$$

Note that Formula (3.3) differs significantly from the corresponding expression in p. 681 of [8] and softens the bootstrapability condition.

### 3.2 The construction for ciphertexts

We now translate the preceding procedure in terms of operations on the ciphertext  $(a, b)$ , which encrypts  $\pi_q(\mu)$  for some  $\mu \in \mathbb{T}_{p_i}$  with a key  $s$ . Note that, in practice, it may have been obtained from a keyswitch operation from another key  $\hat{s}$  to this key  $s$ . We emphasize that the collapsing technique described below is primarily aimed at reducing the rounding errors, as compared to the original formulation in [3]. As observed in [7], it may also have the side-effect to reduce the computational cost of the bootstrap. The components  $s_j$  of the secret key  $s$  are assumed to be taken randomly from the set<sup>5</sup>  $\mathbb{S}$  of integers with cardinal  $K$  possibly greater or equal than 3. As aforementioned, we group these components in

<sup>5</sup>Note that nothing prevents us from considering  $s'$  and  $s$  in different key sets.

vectors of  $m$  elements (collapsing). For the sake of simplicity, we suppose here that  $m$  divides  $n$  and denote, on the one hand

$$\tilde{s}_k = (s_{m(k-1)+1}, s_{m(k-1)+2}, \dots, s_{mk}) \in \mathbb{S}^m, \quad k = 1, \dots, n/m, \quad (3.4)$$

and on the other hand

$$\tilde{a}_k = (a_{m(k-1)+1}, a_{m(k-1)+2}, \dots, a_{mk}) \in \mathbb{T}_q^m, \quad k = 1, \dots, n/m. \quad (3.5)$$

Using the notation  $\cdot$  for the Euclidean scalar product on both  $\mathbb{R}^n$  and  $\mathbb{R}^m$ , we then have

$$\mu + e = b - a \cdot s = b - \sum_{j=1}^{n/m} \tilde{a}_j \cdot \tilde{s}_j.$$

It is important to note at this stage that we round partial sums  $\tilde{a}_k \cdot \tilde{s}_k$  and not individual products  $a_k s_k$  as it is customary [5, 3, 4]. This leads to the (improved) approximation

$$[2N(\mu + e)] \approx - \sum_{k=1}^{n/m} \sum_{\tilde{j} \in \mathbb{S}^m} \delta_{\tilde{j}, \tilde{s}_k} \bar{a}_{k, \tilde{j}} = - \sum_{k=1}^{n/m} \bar{a}_{k, \tilde{s}_k} =: \alpha, \quad (3.6)$$

where we denote  $\delta_{\tilde{i}, \tilde{j}}$ , for  $(\tilde{i}, \tilde{j}) \in \mathbb{S}^m \times \mathbb{S}^m$ , the symbol with value 1 if  $\tilde{i} = \tilde{j}$  and 0 otherwise, and where

$$\bar{a}_{1, \tilde{j}} = [2N\tilde{a}_1 \cdot \tilde{j} - 2Nb], \quad \bar{a}_{k, \tilde{j}} = [2N\tilde{a}_k \cdot \tilde{j}] \quad \text{for } k = 2, \dots, n/m \text{ and } \tilde{j} \in \mathbb{S}^m.$$

Note that the sum in (3.6) is valid for all  $m$  dividing  $n$ , in particular for  $m = 1$ , where we recover the usual expression, as seen in [3] for instance, or for  $m = n$ , where the two sides of the equation then becomes rigorously equal. We finally observe that

$$X^\alpha = \prod_{k=1}^{n/m} X^{-\bar{a}_{k, \tilde{s}_k}} = \prod_{k=1}^{n/m} \sum_{\tilde{j} \in \mathbb{S}^m} \delta_{\tilde{j}, \tilde{s}_k} X^{-\bar{a}_{k, \tilde{j}}} = \prod_{k=1}^{n/m} H_k(X) \quad (3.7)$$

with

$$H_k(X) = \sum_{\tilde{j} \in \mathbb{S}^m} \delta_{\tilde{j}, \tilde{s}_k} X^{-\bar{a}_{k, \tilde{j}}} \in \mathbb{Z}_N[X], \quad k = 1, \dots, n/m, \quad (3.8)$$

so that  $X^\alpha \cdot v(X)$  can be computed as the result of  $n/m$  successive modular products  $\mathbb{Z}_N[X] \cdot \mathbb{T}_N[X]$  applied from the right to the left

$$X^\alpha \cdot v(X) = H_{n/m}(X) \dots (H_2(X) \cdot (H_1(X) \cdot v(X))) \dots \quad (3.9)$$

The complete bootstrap procedure then involves two steps:

1. a blind rotate operation that computes a  $\text{TRLWE}_{\hat{s}}$ -encryption of  $X^\alpha \cdot v(X)$  for an appropriate  $s(X)$ ;
2. an extract operation which computes a  $\text{TLWE}_{\hat{s}}$ -encryption of the constant term of  $X^\alpha \cdot v(X)$ , which is the final output of the bootstrap<sup>6</sup>.

The last step is completely standard and does not differ in our implementation from other works [5, 3, 4]. As a consequence, we describe only the first step, namely the blind rotate operation.

<sup>6</sup>The final TLWE key  $\hat{s} \in \mathbb{S}^{kN}$  is a vectorial version of the polynomial key  $\hat{s}(X) \in \mathbb{S}_N[X]^k$ .

### 3.3 Blind rotation

Given TRGSW $_{\hat{s}}$ -encryptions of the  $\delta_{\tilde{j}, \tilde{s}_k}$ , it is straightforward to compute homomorphically the TRGSW $_{\hat{s}}$ -encryptions of the  $H_k(X)$ ,  $k = 1, \dots, n/m$ , according to Formula (3.8) and

$$\text{TRGSW}_{\hat{s}}(H_k) = \bigoplus_{\tilde{j} \in \mathbb{S}^m} \left( X^{-\tilde{a}_{k, \tilde{j}}} \cdot \text{TRGSW}_{\hat{s}}(\delta_{\tilde{j}, \tilde{s}_k}) \right),$$

where the  $\cdot$  symbol stands for the term-by-term homomorphic modular product. The TRLWE $_{\hat{s}}$ -encrypted value  $X^\alpha \cdot v(X)$  can now be homomorphically computed in agreement with Formula (3.9) as

$$\text{TRGSW}_{\hat{s}}(H_{n/m}) \square (\dots (\text{TRGSW}_{\hat{s}}(H_1) \square \text{TRLWE}_{\hat{s}}(v)) \dots).$$

Note that the TRLWE $_{\hat{s}}(v)$  is taken as the trivial noise-free zero-mask  $(0, \dots, 0, v(X))$ .

## 4 Error estimate of the bootstrap output

Prior to the statement of the main result of this section, introduce two notations. For all polynomial  $P$ ,  $\text{coeff}_i(P)$  denotes its  $i$ -th coefficient, and for all integer  $B$ , we denote  $\xi_B = (3 \cdot (-1)^B + 1)/2$  (i.e.  $\xi_B = 2$  if  $B$  is even and  $\xi_B = -1$  if  $B$  is odd). Then, the main result of this section is the following

**Proposition 4.1** *Assume that  $s \in \mathbb{S}^n$  with  $K = |\mathbb{S}|$ , consider an integer  $1 \leq m \leq n$  dividing  $n$  and denote by  $BK = (BK_{i, \tilde{j}})_{1 \leq i \leq n/m, \tilde{j} \in \mathbb{S}^m}$ , the bootstrap key defined as*

$$BK_{i, \tilde{j}} = \text{TRGSW}_{\hat{s}}(\delta_{\tilde{j}, \tilde{s}_i}), \quad 1 \leq i \leq n/m, \quad \tilde{j} \in \mathbb{S}^m$$

where all the errors have been sampled according to a discrete normal distribution with the same standard deviation  $\sigma_{BK}$  and where

$$\tilde{s}_i = (s_{m(i-1)+1}, s_{m(i-1)+2}, \dots, s_{mi}), \quad 1 \leq i \leq n/m, \quad \tilde{j} \in \mathbb{S}^m.$$

Then (under independence assumptions precised in the proof) the following estimate for the error  $\mathcal{E}_{\text{Boot}}$  of the bootstrap output holds:

$$\text{Var}(\text{coeff}_i(\mathcal{E}^{\text{Boot}})) = \frac{n}{m} \left( 1 + \sum_{j=1}^{\mathbf{k}} \|\hat{s}_j\|_2^2 \right) \frac{B^{-2\ell}}{12} + \frac{n}{m} (\mathbf{k} + 1) \ell N \frac{B^2 + \xi}{12} K^m \sigma_{BK}^2,$$

for  $i = 0, \dots, N - 1$ .

**Remark 4.2** *If we regard the key  $\hat{s}$  as a random variable, and not as a vector of fixed polynomials, the same proof leads to*

$$\text{Var}(\text{coeff}_i(\mathcal{E}^{\text{Boot}})) = \frac{n}{m} \left( 1 + \sum_{j=1}^{\mathbf{k}} \mathbb{E}(\|\hat{s}_j\|_2^2) \right) \frac{B^{-2\ell}}{12} + \frac{n}{m} (\mathbf{k} + 1) \ell N \frac{B^2 + \xi}{12} K^m \sigma_{BK}^2.$$

*Proof.* It is easy to show that the error of an external product of a TRGSW $_{\hat{s}}$ -ciphertext by a TRLWE $_{\hat{s}}$ -ciphertext  $c$  satisfies the following equality

$$\text{Err}(\text{TRGSW}_{\hat{s}}(\nu) \square c) = \nu \text{Err}(c) - \nu \varphi_{\hat{s}}(\delta) + \varphi_{\hat{s}}(\text{dec}_{B,\ell}(c)Z),$$

where the so-called *phase*-function  $\varphi_{\hat{s}}$  is defined for  $c = (a, b) \in \mathbb{T}_{N,q}[X]^{\mathbf{k}+1}$  as

$$\varphi_{\hat{s}}(c)(X) = b(X) - \sum_{j=1}^{\mathbf{k}} a_j(X) \hat{s}_j(X),$$

where

$$\delta = c - \text{dec}_{B,\ell}(c)H_{B,\ell}, \quad \|\delta\|_{\infty} \leq B^{-\ell}/2,$$

and where we have denoted

$$\text{TRGSW}_{\hat{s}}(\nu) = Z + \nu H_B^{\ell} \in \mathcal{M}_{(\mathbf{k}+1)\ell, \mathbf{k}+1}. \quad (4.1)$$

We also define the error associated to this TRGSW ciphertext as the vector

$$\text{Err}(\text{TRGSW}_{\hat{s}}(\nu)) = Z(-s(X), 1)^T.$$

Now, denote  $c^{(0)} = \text{TRLWE}_{\hat{s}}(v(X))$  and, for  $k = 1, \dots, n/m$ , we set

$$c^{(k)} = \text{TRGSW}_{\hat{s}}(H_k) \square c^{(k-1)},$$

where

$$\text{TRGSW}_{\hat{s}}(H_k) = Z^{(k)} + \nu_k H_{B,\ell} = \bigoplus_{\tilde{j} \in \mathbb{S}^m} \left( X^{-\bar{a}_{k,\tilde{j}}} \cdot BK_{k,\tilde{j}} \right)$$

is a TRGSW $_{\hat{s}}$ -encryption of  $\nu_k := X^{-\bar{a}_{k,\tilde{s}_k}}$ . If we set

$$\delta^{(k)} = c^{(k)} - \text{dec}_{B,\ell}(c^{(k)})H_{B,\ell}, \quad k = 1, \dots, n/m,$$

we obtain the following recurrence relation

$$\begin{aligned} \text{Err}(c^{(k)}) &= \nu_k \text{Err}(c^{(k-1)}) - \nu_k \varphi_{\hat{s}}(\delta^{(k-1)}) + \varphi_{\hat{s}}(\text{dec}_{B,\ell}(c^{(k-1)})Z^{(k-1)}) \\ &= \nu_k \text{Err}(c^{(k-1)}) - \nu_k \left( \delta_{\mathbf{k}+1}^{(k-1)} - \sum_{j=1}^{\mathbf{k}} \delta_j^{(k-1)} \hat{s}_j \right) \\ &\quad + \sum_{r=1}^{(\mathbf{k}+1)\ell} \text{dec}_{B,\ell}(c^{(k-1)})_r \sum_{\tilde{j} \in \mathbb{S}^m} X^{-\bar{a}_{k,\tilde{j}}} \text{Err}(BK_{k-1,\tilde{j}})_r \end{aligned}$$

where  $Z_r^{(k-1)}$  is the  $r$ -th line of the matrix  $Z^{(k-1)}$  (it is a TRLWE-encryption of 0).

Our main assumption is now that, with a good approximation, the random variables  $\text{Err}(c^{(k-1)})$ ,  $\delta^{(k-1)}$ ,  $\text{dec}_{B,\ell}(c^{(k-1)})$  and  $\text{Err}(BK_{k,\tilde{j}})$  are pairwise independent. Note that each polynomial in these random variables has centered, pairwise independent coefficients, with a uniform variance. Of course, the assumption of independence seems to be strong;

nevertheless, numerical experiments have shown that possible correlations between these random variable do not significantly affect the result.

Furthermore, since  $q$  is very large, it is difficult distinguish a uniform sampling in  $\mathbb{T}_q$  from a uniform sampling in  $(-1/2, 1/2)$ . Hence, with a good approximation again, one can infer from Lemma A.1 in the Appendix that, for all  $0 \leq i \leq N - 1$ ,

$$\text{Var}(\text{coeff}_i(\text{dec}_{B,\ell}(c^{(k-1)})_r)) = \frac{B^2 + \xi_B}{12}, \quad \text{Var}(\text{coeff}_i(\delta_j^{(k-1)})) = \frac{B^{-2\ell}}{12}.$$

Since  $\text{Var}(\text{Err}(BK_{k-1,j}_r)) = \sigma_{BK}^2$ , we get from Lemma A.2 in the Appendix and from our assumptions that

$$\text{Var}(\text{Err}(c^{(k)})) = \text{Var}(\text{Err}(c^{(k-1)})) + \frac{B^{-2\ell}}{12} \left( 1 + \sum_{j=1}^{\mathbf{k}} \|\hat{s}_j\|_2^2 \right) + (\mathbf{k} + 1)\ell N \frac{B^2 + \xi}{12} K^m \sigma_{BK}^2.$$

Taking into account that  $\text{Err}(c^{(0)}) = 0$ , a direct induction leads to the result.  $\square$

## 5 Conditions of correctness of the bootstrap

In this paragraph, we state some deterministic conditions for the bootstrapping operation to be correct. We then estimate the probability that these conditions are satisfied in practice. For the sake of clarity of the presentation, we assimilate in the beginning of this section (until Section 5.2 where the situation encountered in practice  $q = 2^{64}$  is considered) the discrete torus  $\mathbb{T}_q$  with the continuous one  $\mathbb{T}$ . By doing so, we neglect the influence of errors produced by rounding elements of  $\mathbb{T}$  to elements of  $\mathbb{T}_q$ , which can be bounded by  $1/(2q)$  and are thus very small in practice. In order to give a precise definition of correctness, we thus assume that the ciphertext  $c = (a, b) \in \mathbb{T}^{n+1}$  encrypts a value  $\mu \in \mathbb{T}_{p_i}$ , that is to say that

$$b - a \cdot s = \mu + e, \quad \mu \in \mathbb{T}_{p_i},$$

where we assume that the error  $e$  is a normally distributed random variable in  $\mathbb{T}$  with standard deviation  $\sigma_e$ .

**Definition 5.1** *Let  $n$  be the number of components of the secret key  $s \in \mathbb{S}$ ,  $n/m \in \mathbb{N}$  be the number of vectors  $\tilde{s}_k$  of length  $m$  as defined in (3.4) and  $N$  be the degree of polynomials considered in TRLWE and TRGSW ciphertexts. Let us suppose that*

$$w_2(\mathbb{T}_{p_i}) := \min_{\mu \neq \nu \in \mathbb{T}_{p_i}^2} \min_{k \in \mathbb{Z}} \left| \mu - \nu - \frac{k}{2} \right| > \frac{1}{2N}. \quad (5.1)$$

*The bootstrapping procedure is said to be correct with probability  $\mathbb{P}_{\text{corr}}$  if and only if for every ciphertext  $(a, b) \in \mathbb{T}^{n+1}$  with*

$$b = a \cdot s + \mu + e$$

for some  $\mu \in \mathbb{T}_{p_i}$ , we have

$$\mathbb{P}\left(-\sum_{k=1}^{n/m} \bar{a}_{k, \bar{s}_k} \in I_\mu\right) = \mathbb{P}_{corr} \quad (5.2)$$

where

$$I_\mu = \left[2N\left(\mu - \frac{1}{2}w_2(\mathbb{T}_{p_i})\right), 2N\left(\mu + \frac{1}{2}w_2(\mathbb{T}_{p_i})\right)\right] \cap \mathbb{Z} + 2N\mathbb{Z}.$$

Condition (5.1) ensures that it is possible to construct a suitable polynomial  $v(X)$  for the bootstrapping procedure (in particular, the sets  $I_\mu$  and  $N + I_\mu$  for  $\mu \in \mathbb{T}_{p_i}$  are non-empty and do not intersect with each other). Note that whenever

$$-\sum_{k=1}^{n/m} \bar{a}_{k, \bar{s}_k} \in I_\mu$$

the constant coefficient of  $X^\alpha \cdot v(X)$  is precisely  $\mu$  and the bootstrapping procedure delivers the correct result. The condition is sufficient, though not strictly necessary for all  $\mu$ 's. For instance, if  $p_i = 5$  and  $\mu = \frac{1}{5}$ , a necessary and sufficient condition is that

$$-\sum_{k=1}^{n/m} \bar{a}_{k, \bar{s}_k} \in \left[2N\left(\mu - \frac{1}{2}w_2(\mathbb{T}_{p_i})\right), 2N\left(\mu + \frac{3}{2}w_2(\mathbb{T}_{p_i})\right)\right] \cap \mathbb{Z} + 2N\mathbb{Z}$$

and the corresponding interval is strictly larger than  $I_\mu$  for large enough  $N$ . Our aim is now to give lower bounds of the probability  $\mathbb{P}_{corr}$ . To state our main result, we need to recall and introduce a few notations. Given the ciphertext  $(a, b)$  whose  $n$  first components  $a_i$  have been grouped to form the  $\tilde{a}_k \in \mathbb{T}^m$  as described in Section 3.2, let  $\bar{a}_{k, \tilde{j}} = \lfloor 2N(\tilde{a}_k \cdot \tilde{j}) \rfloor$ . For  $\tilde{j} \in \mathbb{S}^m$  and  $k = 2, \dots, n/m$ , we denote

$$X_{1, \tilde{j}} = \bar{a}_{1, \tilde{j}} - 2N\tilde{a}_1 \cdot \tilde{j} + 2Nb \quad \text{and} \quad X_{k, \tilde{j}} = \bar{a}_{k, \tilde{j}} - 2N\tilde{a}_k \cdot \tilde{j}.$$

**Proposition 5.2** *Under the assumptions of Definition 5.1, the bootstrapping of*

$$c = (a_1, \dots, a_n, \sum_{k=1}^n s_k a_k + \mu + e), \quad \mu \in \mathbb{T}_{p_i},$$

where  $a \stackrel{\$}{\leftarrow} \mathbb{T}^n$  and where  $e$  is a normal random variable on  $\mathbb{T}$  with standard deviation  $\sigma_e$ , is correct with probability  $\mathbb{P}_{corr}$  bounded from below by

$$\mathbb{P}_{corr} \geq \frac{2}{\pi} \int_0^\infty \sin((t(\lambda^+ - \lambda^-)) \cos((t(\lambda^+ + \lambda^-))) \left(\text{sinc}\left(\frac{t}{4N}\right)\right)^L \frac{\exp(-\sigma_e^2 t^2 / 2)}{t} dt \quad (5.3)$$

where  $\lambda^\pm = \frac{\lceil 2N\mu \pm Nw_2(\mathbb{T}_{p_i}) \rceil}{2N} - \frac{1}{4N} - \mu$  and  $L$  is the number of non-zero variables among the  $(X_{k, \bar{s}_k})_{k=2, \dots, n/m}$ .

*Proof.* By definition, the bootstrapping of  $c$  is correct if and only if  $(-\sum_{k=1}^{n/m} \bar{a}_{k, \tilde{s}_k}) \in I_\mu$ , that is to say, if and only if there exists  $r \in \mathbb{Z}$  such that

$$\begin{aligned} 2N(\mu - \frac{1}{2}w_2(\mathbb{T}_{p_i})) &\leq - \left[ \sum_{k=2}^{n/m} X_{k, \tilde{s}_k} - 2N\mu - 2Ne \right] + 2rN \\ &< 2N(\mu + \frac{1}{2}w_2(\mathbb{T}_{p_i})). \end{aligned} \quad (5.4)$$

As a matter of fact, one has

$$\begin{aligned} \bar{a}_{1, \tilde{s}_1} &= [2N\tilde{a}_1 \cdot \tilde{s}_1 - 2Nb] \\ &= \left[ 2N\tilde{a}_1 \cdot \tilde{s}_1 - 2N\mu - 2Ne - 2N \sum_{k=1}^{n/m} \tilde{a}_k \cdot \tilde{s}_k \right] \\ &= \left[ -2N\mu - 2Ne - 2N \sum_{k=2}^{n/m} \tilde{a}_k \cdot \tilde{s}_k \right] \\ &= \left[ -2N\mu - 2Ne - \sum_{k=2}^{n/m} \bar{a}_{k, \tilde{s}_k} + \sum_{k=2}^{n/m} \bar{X}_{k, \tilde{s}_k} \right] \end{aligned}$$

so that

$$\sum_{k=1}^{n/m} \bar{a}_{k, \tilde{s}_k} = \left[ -2N\mu - 2Ne + \sum_{k=2}^{n/m} X_{k, \tilde{s}_k} \right].$$

Now, for any  $\alpha, \beta, \gamma \in \mathbb{R}^3$  and  $k \in \mathbb{Z}$ , we have, on the one hand

$$\alpha \leq k < \beta \text{ iff } [\alpha] \leq k \leq [\beta] - 1,$$

and on the other hand

$$-[-\gamma] = k \text{ iff } k - \frac{1}{2} < \gamma \leq k + \frac{1}{2},$$

so that

$$\alpha \leq -[-\gamma] < \beta \text{ iff } [\alpha] - \frac{1}{2} < \gamma \leq [\beta] - \frac{1}{2}.$$

Hence, condition (5.4) is equivalent to the existence of  $r \in \mathbb{Z}$  such that

$$\begin{aligned} \left[ 2N(\mu - \frac{1}{2}w_2(\mathbb{T}_{p_i})) \right] - \frac{1}{2} &< - \sum_{k=2}^{n/m} X_{k, \tilde{s}_k} + 2N\mu + 2Ne + 2rN \\ &\leq \left[ 2N(\mu - \frac{1}{2}w_2(\mathbb{T}_{p_i})) \right] - \frac{1}{2}. \end{aligned}$$

We thus obtain the following necessary and sufficient condition

$$\exists r \in \mathbb{Z}, \quad \lambda^- < -\frac{1}{2N} \sum_{k=2}^{n/m} X_{k, \tilde{s}_k} + e + r \leq \lambda^+$$

where  $\lambda^\pm = \frac{[2N\mu \pm Nw_2(\mathbb{T}_{p_i})]}{2N} - \frac{1}{4N} - \mu$ . We now regard the components  $X_{k, \tilde{s}_k}$ , for  $k = 2, \dots, n/m$  with  $\tilde{s}_k \neq 0$ , as independent variables uniformly distributed in  $[-\frac{1}{2}, \frac{1}{2}]$ . We wish to find the probability that the bootstrap is correct, that is to say to compute

$$I := \mathbb{P} \left( \bigcup_{r \in \mathbb{Z}} \left\{ \lambda^- < -\frac{1}{2N} \sum_{k=2}^{n/m} X_{k, \tilde{s}_k} + e + r < \lambda^+ \right\} \right).$$

Denoting  $(r_\ell)_{\ell=1, \dots, L}$  the indices of non-zero variables among the  $(X_{k, \tilde{s}_k})_{k=2, \dots, n/m}$ ,  $\lambda_r^\pm = \lambda^\pm - r$  and

$$\mathcal{X} = -\frac{1}{2N} \sum_{\ell=1}^L X_{r_\ell, \tilde{s}_{r_\ell}} + e,$$

we finally have that

$$I = \sum_{r \in \mathbb{Z}} \mathbb{P}(\lambda_r^- < \mathcal{X} < \lambda_r^+). \quad (5.5)$$

Note indeed that the intervals  $[\lambda_r^-, \lambda_r^+]$ ,  $r \in \mathbb{Z}$  do not intersect as

$$|\lambda^+ - \lambda^-| \leq \max \left( w_2(\mathbb{T}_{p_i}), \frac{1}{N} - w_2(\mathbb{T}_{p_i}) \right) < 1.$$

Using the characteristic functions

$$\varphi(t) = \mathbb{E}(\exp(it e)) \quad \text{and} \quad \varphi_{\mathcal{X}}(t) = \mathbb{E}(\exp(it \mathcal{X}))$$

we have, owing to Gil-Pelaez theorem, that

$$\mathbb{P}(\mathcal{X} \leq x) = \frac{1}{2} - \frac{1}{\pi} \int_0^\infty \frac{\text{Im}[e^{-itx} \varphi_{\mathcal{X}}(t)]}{t} dt,$$

where

$$\varphi_{\mathcal{X}}(t) = \left( \prod_{\ell=1}^L \mathbb{E} \left( \exp \left( -i \frac{t}{2N} X_{r_\ell, \tilde{s}_{r_\ell}} \right) \right) \right) \varphi(t) = \left( \prod_{\ell=1}^L \text{sinc}(t/(4N)) \right) \varphi(t).$$

Then, taking into account the symmetry of  $e$  (and thus the fact that  $\varphi$  is real-valued and even)

$$\mathbb{P}(\mathcal{X} \leq x) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \sin(tx) \left( \frac{\sin(t/(4N))}{t/(4N)} \right)^L \frac{\varphi(t)}{t} dt$$

so that (see Equation (5.5))

$$\begin{aligned} I &= \frac{2}{\pi} \sum_{r \in \mathbb{Z}} \int_0^\infty \sin((t(\lambda^+ - \lambda^-)) \cos((t(\lambda_r^+ + \lambda_r^-))) \left( \frac{\sin(t/(4N))}{t/(4N)} \right)^L \frac{\varphi(t)}{t} dt \\ &\geq \frac{2}{\pi} \int_0^\infty \sin((t(\lambda^+ - \lambda^-)) \cos((t(\lambda^+ + \lambda^-))) \left( \frac{\sin(t/(4N))}{t/(4N)} \right)^L \frac{\varphi(t)}{t} dt. \end{aligned}$$

□

**Remark 5.3** *The term for  $r = 0$  is the only one that matters in the sum. As a matter of fact, since*

$$e - \frac{L}{4N} \leq \mathcal{X} \leq e + \frac{L}{4N}$$

*one has*

$$\mathbb{P}(\lambda_r^- < \mathcal{X} < \lambda_r^+) \leq \mathbb{P}\left(\lambda_r^- - \frac{L}{4N} - r \leq e \leq \lambda_r^+ + \frac{L}{4N} - r\right)$$

*Note that the intervals on the right do not intersect as soon as*

$$\lambda^+ - \lambda^- + \frac{L}{2N} \leq 1$$

*a condition satisfied if  $w_2(\mathbb{T}_{p_i}) + \frac{L+1}{2N} \leq 1$  and which can be checked in all practical situations. We then have*

$$\sum_{r \neq 0} \mathbb{P}(\lambda_r^- < \mathcal{X} < \lambda_r^+) \leq \mathbb{P}\left(|e| \geq 1 - \frac{w_2(\mathbb{T}_{p_i})}{2} - \frac{L+1}{4N}\right)$$

*Assume now that  $e$  follows a Gaussian law with standard deviation  $\sigma_e$ , then*

$$\sum_{r \neq 0} \mathbb{P}(\lambda_r^- < \mathcal{X} < \lambda_r^+) \leq 1 - \operatorname{erf}\left(\frac{\lambda}{\sqrt{2}\sigma_e}\right), \quad \text{with } \lambda = 1 - \frac{w_2(\mathbb{T}_{p_i})}{2} - \frac{L+1}{4N}$$

*where the erf-function is the usual error function*

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt.$$

*Typical values for the parameters are (see section below)  $N = 1024, L = 210, p_i = 7, \sigma_e = 0.0016$ , which yield (knowing that here we have  $w_2(\mathbb{T}_{p_i}) = 1/(2p_i)$ )*

$$\sum_{r \neq 0} \mathbb{P}(\lambda_r^- < \mathcal{X} < \lambda_r^+) \leq 1 - \operatorname{erf}(403) \approx 6.5103937 \times 10^{-70537}$$

*which is an extremely small probability.*

## 5.1 Comparison with the law of probability obtained by the central limit theorem

If, instead of the detailed computations undertaken in previous subsection, one regards the random variable  $\mathcal{X}$  as a Gaussian variable with variance

$$\sigma_{\mathcal{X}}^2 = \sigma_e^2 + \frac{L}{48N^2},$$

as the central limit theorem predicts in the limit where  $n$  and  $L$  are large, then the law of probability of  $\mathcal{X}$  is simply approximated by

$$\mathbb{P}(\mathcal{X} \leq \lambda) \approx \frac{1}{2} \left( 1 + \operatorname{erf}\left(\frac{\lambda}{\sqrt{2}\sigma_{\mathcal{X}}}\right) \right).$$

As an indication of how this approximation by the central limit theorem is accurate, we plot on Figure 1 the curves corresponding to the two expressions obtained here and in previous subsection, respectively in red and blue colors on the graph.

Figure 1: Probability of correctness given by characteristic function (blue) or by the central limit approximation (red).

It is clear that in most regimes, i.e. for probability of correctness that are not too stringent, the central limit approximation is enough. Below  $10^{-12}$  one benefits from the better approximation obtained by characteristic functions. In next subsection, we will systematically use this improved approximation to calibrate our parameters, not only because it leads to more accurate results, but also because it is a *proven* lower bound, that the other approximation is not.

## 5.2 Calibration of parameters for the bootstrap

In this subsection, we use the lower bound obtained above to obtain various curves for the parameters  $p_i$ ,  $m$ ,  $N$ ,  $\sigma_e$ . The number of non-zero values  $L$  is in average  $\frac{n}{m}(1 - K^{-m})$  for keys with  $K = |\mathbb{S}|$  values and since the results are not very sensitive to the value of  $L$  in the neighbourhood of this value, we shall always consider

$$L = \frac{n}{m}(1 - K^{-m}).$$

Only two instances of  $N$  are considered here, namely  $N = 1024$  and  $N = 2048$ , and we shall take  $n = 420$  and  $m = 1, 2, 3, 4, 5, 6, 7$ , corresponding to  $L = 210, 158, 123, 98, 81, 69, 60$  and  $K = 2$ . To plot the curves of Figures 2 and 3, we have taken  $p_i = 27$  and  $\mu = 1/27$  for the previous list of values of  $m$ .

In order to design a secure system, it is known that  $\sigma_e$  should be greater than a certain threshold

$$\sigma_e \geq \sigma_{TH}$$

where a practical value of  $\sigma_{TH}$  can be determined with the help of the lattice estimator designed by Martin R. Albrecht's team<sup>7</sup>. The values obtained by running this estimator

<sup>7</sup><https://lattice-estimator.readthedocs.io/en/latest/>

Figure 2: Probability of correctness given by characteristic function or by the central limit approximation in terms of  $\sigma_e$ . Values obtained with  $N = 1024$  and  $m$  from 1 to 4 (left) and 4 to 7 (right).

with  $n = 420$ ,  $q = 2^{64}$  and  $K = 2$  are reported below:

- for 100 bits of security:  $\sigma_{TH} = 0.00032$ ;
- for 128 bits of security:  $\sigma_{TH} = 0.003$ .

The two thresholds appear as two vertical lines on all curves of Figures 2 and 3.

## A Appendix

In this section, we state two elementary lemmas which are used in the proof of Proposition 4.1. We state the first one without explicit proof as it can be obtained by a simple induction.

**Lemma A.1** *Let  $x$  be random variable uniformly distributed in the interval  $(-1/2, 1/2)$  and let  $(x_i)_{1 \leq i \leq \ell}$  and  $\delta_\ell$  be the random variables obtained by decomposing  $x$  in the basis  $B$  according to the following algorithm:*

$$\tilde{x}_1 = x, \quad x_i = -\lfloor -B\tilde{x}_i \rfloor, \quad \tilde{x}_{i+1} = B\tilde{x}_i - x_i, \quad \text{for } i = 1, \dots, \ell,$$

and

$$\delta_\ell = B^{-\ell} \tilde{x}_{\ell+1}.$$

Then  $\delta_\ell$  is uniformly distributed in the interval  $(-B^{-\ell}/2, B^{-\ell}/2)$  and the  $x_i$ 's are discrete random variables with values in  $\{-\lfloor B/2 \rfloor, -\lfloor B/2 \rfloor + 1, \dots, \lfloor B/2 \rfloor\}$  obeying the following law

$$\mathbb{P}(x_i = k) = \frac{1}{B}, \quad \text{for } -\lfloor B/2 \rfloor < k < \lfloor B/2 \rfloor,$$

Figure 3: Probability of correctness given by characteristic function or by the central limit approximation in terms of  $\sigma_e$ . Values obtained with  $N = 2048$  and  $m$  from 1 to 3 (left) and 4 to 6 (right).

$$\mathbb{P}(x_i = -\lfloor B/2 \rfloor) = \mathbb{P}(x_i = \lfloor B/2 \rfloor) = -\lfloor B/2 \rfloor/B + 1/2B + 1/2.$$

In particular

$$\text{Var}(x_i) = \frac{B^2 + \xi_B}{12} \quad \text{with} \quad \xi_B = (3 \cdot (-1)^B + 1)/2.$$

**Lemma A.2** Consider a random polynomial  $P \in \mathbb{Z}_N[X]$  whose coefficients are pairwise independent, centered and have the same variance  $\sigma_P^2$ . Then, for all non-random polynomial  $Q \in \mathbb{Z}_N[X]$  and all  $i \in \{0, \dots, N-1\}$ , we have

$$\mathbb{E}((PQ)_i) = 0, \quad \text{Var}((PQ)_i) = \sigma_P^2 \|Q\|_2^2.$$

If  $Q$  is random and independent of  $P$ , we have

$$\mathbb{E}((PQ)_i) = 0, \quad \text{Var}((PQ)_i) = \sigma_P^2 \mathbb{E}(\|Q\|_2^2).$$

*Proof.* The main argument of the proof stems from the periodicity of the coefficients of  $P$  and  $Q$  as elements of  $\mathbb{Z}[X]/(X^N + 1)$ . As a matter of fact, given  $P(X) = \sum_{i=0}^{N-1} P_i X^i$  and  $Q(X) = \sum_{i=0}^{N-1} Q_i X^i$ , one has

$$(PQ)_i = \sum_{j=0}^{N-1} P_j Q_{i-j}.$$

As a consequence, if  $Q$  is non random and  $\mathbb{E}(P_j) = 0$ , we have

$$\mathbb{E}((PQ)_i) = \sum_{j=0}^{N-1} \mathbb{E}(P_j) Q_{i-j} = 0,$$

$$\begin{aligned}
\mathbb{E}((PQ)_i)^2 &= \mathbb{E} \left( \sum_{j,j'} P_j Q_{i-j} P_{j'} Q_{i-j'} \right) \\
&= \sum_j \mathbb{E}(P_j^2) Q_{i-j}^2 + \sum_{j \neq j'} \mathbb{E}(P_j) \mathbb{E}(P_{j'}) Q_{i-j} Q_{i-j'} \\
&= \sum_j \text{Var}(P_j) Q_{i-j}^2 = \sigma_P^2 \|Q\|_2^2.
\end{aligned}$$

If  $Q$  is random and is independent of  $P$ , we have again

$$\mathbb{E}((PQ)_i) = \sum_{j=0}^{N-1} \mathbb{E}(P_j) \mathbb{E}(Q_{i-j}) = 0,$$

$$\begin{aligned}
\mathbb{E}((PQ)_i)^2 &= \mathbb{E} \left( \sum_j \sum_{j'} P_j Q_{i-j} P_{j'} Q_{i-j'} \right) \\
&= \sum_j \mathbb{E}(P_j^2) \mathbb{E}(Q_{i-j}^2) + \sum_j \sum_{j' \neq j} \mathbb{E}(P_j) \mathbb{E}(P_{j'}) \mathbb{E}(Q_{i-j} Q_{i-j'}) \\
&= \sum_j \mathbb{E}(P_j^2) \mathbb{E}(Q_{i-j}^2) = \sigma_P^2 \mathbb{E}(\|Q\|_2^2).
\end{aligned}$$
